ABSTRACT

Cladistic analysis of ndhF sequences identifies eight major bromeliad clades arranged in ladderlike fashion. The traditional subfamilies Tillandsioideae and Bromelioideae are monophyletic, but Pitcairnioideae are paraphyletic, requiring the description of four new subfamilies, recircumscription of Pitcairnioideae and Navioidae, the sinking of Ayensua, and description of the new genus Sequencia. Brocchinioideae are basalmost, followed by Lindmanioideae, both restricted to the Guayan Shield. Next is an unresolved trichotomy involving Hechtioideae from Central America, Tillandsioideae, and the remaining bromeliads in subfamilies Navioidae, Pitcairnioideae, Puyoideae, and Bromelioideae. Bromeliads arose as C₃ terrestrial plants on moist infertile sites in the Guayan Shield roughly 70 Mya, spread centripetally in the New World, and reached tropical West Africa (Pitcairnia feliciana) via long-distance dispersal about 10 Mya. Modern lineages began to diverge from each other 19 Mya and invaded drier areas in Central and South America beginning 15 Mya, coincident with a major adaptive radiation involving the repeated evolution of epiphytism, CAM photosynthesis, impounding leaves, several features of leaf/trichome anatomy, and accelerated diversification at the generic level. This “bromeliad revolution” occurred after the uplift of the northern Andes and shift of the Amazon to its present course. Epiphytism may have accelerated speciation by increasing ability to colonize along the length of the Andes, while favoring the occupation of a cloud-forest landscape frequently dissected by drier valleys. Avian pollination (mainly by hummingbirds) evolved at least twice ca. 13 Mya; entomophily was ancestral. Hechtia, Abromeitiella-Deuterocohnia-Dyckia-Encholirium, and Puya exhibit a remarkable pattern of concerted convergence in six anatomical and physiological leaf traits adapted to drought.

Key words: Brazilian Shield, Brocchinia, correlated evolution, phylogeography.

INTRODUCTION

The largely Neotropical family Bromeliaceae (56 genera, 2600 species) has traditionally been divided into three subfamilies: Pitcairnioideae with winged (or rarely naked) seeds, Tillandsioideae with plumose seed appendages, and Bromelioideae with baccate fruits (Smith and Downs 1974, 1977, 1979; Smith and Till 1998). Beginning 15 years ago, several studies attempted to infer relationships among these subfamilies and their constituent genera using morphological and (especially) molecular data (see Gilmartin and Brown 1987; Clark and Clegg 1990; Givnish et al. 1990, 1992; Ranker et al. 1990; Clark et al. 1993). Early progress was limited, partly because bromeliads exhibit substantial homoplasy in morphology (e.g., Varadarajan and Gilmartin 1988), partly because they occupy an isolated taxonomic position with no clear outgroup with which to polarize character-states (Gilmartin and Brown 1987; Terry et al. 1997a; Givnish et al. 2000; Pires and Sytsma 2002), and partly because their chloroplast DNA evolves at an exceptionally slow rate (Gaut et al. 1992, 1997; Givnish et al. 2004, 2006).

Seven years ago, Terry et al. (1997a) revolutionized bromeliad systematics by obtaining sequences of the rapidly evolving, chloroplast-encoded ndhF gene for several genera representing each of the putative subfamilies. They found that Brocchinia acuminata—a placeholder for a genus traditionally viewed as pitcairnioid—occupies a position at the base of the family; Tillandsioideae are monophyletic and form the next divergent branch. The remaining pitcairnioids studied are paraphyletic, with single species of Dyckia, Encholirium, Fosterella, Pitcairnia, and Navia forming one clade, and Puya sister to a monophyletic Bromelioideae. This study was a fundamental contribution, but fell short of being a comprehensive basis for analyzing phylogeny, ecological diversification, and historical biogeography across bromeliads, because more than half the pitcairnioid genera were not sampled, including most of the critical genera endemic to the Guayan Shield in northern South America (Givnish et al. 1997), as well as the only bromeliad found outside the New World, Pitcairnia feliciana of West Africa (Porembski and Barthlott 1999).

Horres et al. (2000) analyzed nucleotide variation in the trnL intron of cpDNA across 62 bromeliad species and 32 genera. They found three major clades in an unresolved trichotomy: (1) single species of Ayensua and Brocchinia; (2) three species of Hechtia; and (3) all other bromeliad genera sampled. The last group itself entailed an unresolved polytomy of five additional clades, including a monophyletic Bromelioideae. Resolution was limited because they detected only 73 informative base substitutions among 62 taxa, compared with 71 substitutions among many fewer taxa in the ndhF study by Terry et al. (1997a). Several crucial pitcairnioid taxa were again not examined, including almost all of the Guayan Shield endemics. Horres et al. (2000) did, however, sequence P. feliciana and showed that it was related to other members of the same genus. Crayn et al. (2000) investigated relationships among 11 of the 16 pit-
carniioid genera using nucleotide data for roughly half of the cpDNA matK gene, but their results provided little phylogenetic structure beyond individual genera in most cases, recognizing a clade with a nine-way polytomy being sister to *Hechtia*, using tillandsioideans as an outgroup. Reinert et al. (2003) used these same matK sequences to analyze relationships among only pitcairnioid genera, and found weak support for *Hechtia* rather than *Brocchinia* being the sister to all pitcairnioids. Crayn et al. (2004) conducted a combined analysis of matK and rps16 sequences for 48 bromeliad taxa; while their results were somewhat better resolved than those of Givnish et al. (2000) and Reinert et al. (2003), many large-scale relationships remained unresolved. They identified *Brocchinia* as sister to the rest of the family, which they resolved as one major 4-way polytomy, including *Hechtia*, *Navia phelpsiae* L. B. Sm.–*Cottendorfia*, Tillandsioideae, and a 5-way polytomy, including all of the other taxa sampled (*Pitcairnia* in part, *Fosterella*, *Dyckia–Encholirium–Deuterocohnia*, *Navia igneosica* L. B. Sm., Steyerm. & H. Rob.–*Pitcairnia* in part, and Bromelioidae).

To reconstruct phylogenetic relationships within Bromeliaceae, we present a molecular phylogeny based on nucleotide variation in *ndhF*, a relatively large (ca. 2200 bp) gene in the chloroplast genome that evolves at a substantially faster rate than *rbcL*. (Gaut et al. 1997; Terry et al. 1997; Givnish et al. 2000, 2004; Fires et al. 2006). To clarify overall relationships within the family as a whole, we analyze *ndhF* sequence data for a highly inclusive sample of taxa, including representatives of all three subfamilies and all but two of the pitcairnioid genera, including those endemic to the Guayana Shield. We calibrate the resulting tree against the times of origin of other monocot groups based on an *ndhF* phylogeny across monocots (Givnish et al. 2006) and the inferred divergence of *Acorus* from other monocots 134 million years ago (Mya) (Bremer 2000). We then use this calibrated phylogeny to (1) analyze evolutionary relationships within the family and propose a revised infrafamilial classification, (2) infer the timing of cladogenetic events within the family, (3) relate the latter to datable events in geographic and climatic history, (4) evaluate ancient vicariance vs. recent long-distance dispersal as potential mechanisms accounting for the distribution of *P. feliciana* in West Africa, (5) analyze where the family may have arisen, and (6) correlate the spread of the family outside its area of origin with features related to its extensive adaptive radiation, including the rise of such ecological innovations as epiphytism and CAM photosynthesis.

MATERIALS AND METHODS

**Taxon Sampling and Outgroup Analysis**

We included 58 *ndhF* sequences in our analysis, including 35 for taxa representing all major groups of Bromeliaceae, and 16 for taxa representing all three subfamilies of Rappateaceae (Table 1). Only two genera of Pitcairnioidae were not sampled: *Connellia* and *Steyerbromelia*. Based on morphology, *Connellia* appears closely related to *Lindmania* and possibly embedded within it, differing mainly in the possession of large, colorful inflorescence bracts; *Steyerbromelia* appears closely related to *Brewcaria* and *Navia*, differing from them in having winged seeds or minute petal appendages, respectively (Holst 1997). All genera of Tillandsioideae and Bromelioidae not included in our survey but previously sequenced for *ndhF* (e.g., *Mezobromelia, Cryptanthus*) have been shown to belong to these two monophyletic subfamilies (Terry et al. 1997a, b).

To maximize the resolution of relationships within the ingroup while minimizing artifacts due to a poor sampling of outgroups (Sytsma and Baum 1996), we used seven outgroup taxa representing Mayacaceae, Typhaceae, Flagellariaceae, Joinvilleaceae, and Poaceae. Based on a cladistic analysis of *ndhF* cpDNA sequences across monocots, Givnish et al. (2006) found that Typhaceae are sister to Bromeliaceae at the base of order Poales (sensu APG II 2003), with Rapataceae next divergent. Mayacaceae, Ericaceae, and Xyridaceae are sister to Cyperaceae–Thurniaceae; together, these members of the sedge alliance are sister to the remaining families of Poales, including Flagellariaceae, Joinvilleaceae, and Poaceae among others. Based on these inferred relationships, we used species of Flagellaria, Joinvillea, and basal grasses as super-outgroups to polarize character-states within Bromeliaceae and their immediate relatives. Appendix 1 gives authorities for all generic names mentioned in the text. Table 1 gives authorities for specific epithets of the taxa sequenced.

**DNA Extraction, Amplification, and Sequencing**

Total DNAs were isolated from fresh leaves, or material frozen at −80°C or dried in contact with silica gel, using the CTAB (hexadecyltrimethylammonium bromide) technique as modified by Smith et al. (1991). We amplified and cycle-sequenced *ndhF* using standard procedures, and then edited sequences for the forward and reverse strands using standard techniques (Givnish et al. 2000). Sequences were visually aligned following Baum et al. (1994). GenBank accession numbers were acquired for all new sequences obtained; the remaining sequences were downloaded from GenBank (Table 1).

**Phylogenetic Analyses**

We inferred relationships from *ndhF* sequences using maximum parsimony in PAUP* vers. 4.0b10 (Swofford 2002). Nucleotide positions were considered multistate, unordered characters of equal weight. Unknown nucleotides were treated as uncertainties. Indels were excluded from analysis, because they generally only supported relationships that were already supported by mutations at the level of individual nucleotides. To search for multiple islands of most parsimonious trees (Maddison 1991), we conducted heuristic searches seeded with 500 random addition sequences, using TBR swapping with MULPARS activated. We formed the strict consensus of the shortest trees obtained, and employed bootstrap analysis (Felsenstein 1985) to evaluate the relative support for each node. To produce a tree that could be calibrated against the geological ages of known fossils of other monocot groups, we substituted our selection of bromeliad taxa for the smaller group included in the across-monocot *ndhF* data set of Givnish et al. (2006). Heuristic searches identical to those just described were then conducted, using Ceratophyllum as an outgroup.
Molecular Clocks and Historical Biogeography

To test whether \textit{ndhF} evolves in clocklike fashion within Bromeliaceae, we pruned nonfamily members from the maximum-parsimony trees and set the earliest-divergent clade as the outgroup. We then calculated the log likelihoods of these trees with and without enforcing a molecular clock using a six-parameter, fully time-reversible model in PAUP*, employing a gamma distribution of rates fit to quartile means. To test for significant deviations from a molecular clock, we compared twice the difference of these log likelihoods with the \(\chi^2\) distribution with \(n - 2\) degrees of freedom (d.f.), where \(n\) is the number of taxa included in the analysis (Felsenstein 1994; Sanderson 1997). We calculated the mean \(\pm\) SD of branch lengths from the stem group of each family to all the terminal taxa as alternative measures of regularity in evolutionary rates (Givnish et al. 1999, 2000).

We converted one of the maximum-parsimony trees to ultrametric form—in which the lengths of all branches from the root are identical—using penalized likelihood (PL) in the computer program \textsc{r8s} (Sanderson 2002). PL averages local differences in the rate of DNA evolution on different branches, taking into account the topology of branching; PL differs from nonparametric rate smoothing (NPRS) (Sanderson 1997) in that it assigns a penalty for rate changes among branches which are too rapid or frequent, based on a smoothness parameter. If the smoothness parameter is large, then PL approaches a clocklike model of molecular evolution; if the smoothness parameter is small, then PL approaches NPRS. NPRS behaves well in trees with substantial rate variation, but suffers when rates are clocklike or nearly so (Sanderson 2002, pers. comm.). We employed the cross-verification algorithm in \textsc{r8s} to find the optimal value of the smoothness parameter, minimizing the sum of the squared deviations between observed and expected branch lengths derived through jackknifing each individual branch (Sanderson 2002). The smoothness parameter was varied from \(10^0\) to \(10^1\) in steps of 0.25 in the exponent. For comparative purposes, we also used NPRS, Langley-Fitch molecular clocks (Langley and Fitch 1974), and lineage-specific mutation rates (Givnish et al. 1999, 2000) to estimate ages on a pruned monocot tree, consisting solely of Bromeliaceae and its immediate sister group \textit{Typha–Sparganium}. Dates of divergence within the pruned tree were calibrated by setting the age of the stem group of \textit{Typha–Sparganium} equal to 69.5 Ma, based on the oldest known fossils for the latter group (Herendeen and Crane 1995; Bremer 2000).

We calibrated the cross-verified PL tree against absolute time by equating the time at which Acorales diverged from other monocots to 134 Ma, based on Bremer’s (2000) phylogenetic analysis. We constrained the ages of the stem groups of Poaceae–Joinvilleaceae–Flagellariaceae–Restionaceae, Typhaceae, Arales, and Tofieldiaceae to be at least 69.5 Ma, and the corresponding times of origin of \textit{Zingiberales} and \textit{Arecales} to be at least 83 and 89.5 Ma, respectively, based on the ages of the oldest documented fossils of each of these groups (Bremer 2000). We had to take this indirect route to calibrating the \textit{ndhF} phylogeny because almost all bromeliads grow in habitats poor for fossil preservation. Indeed, there is only one macrofossil—\textit{Karaptophyllum bromelioides} L. D. Gomez, from Costa Rica 36 Mya—clearly assignable to the family (Smith and Downs 1974; Smith and Till 1998); there is also an unpublished report of bromeliaceous pollen from Panama substantially earlier than that from the Eocene (Benzing 2000). We related the timing of inferred cladogenetic events within Bromeliaceae—including the divergence of \textit{P. feliciana} from its nearest Neotropical relative—to the times of uplift and dissection of the tepuis of the Guayana Shield, formation of the Amazon basin, and uplift of the Andes (Ghosh 1985; Briceño and Schubert 1990; Briceño et al. 1990; Siddier and Mendoza 1991; Stallard et al. 1991; Hoorn 1994; Hoorn et al. 1995; Briceño 1995; Edmond et al. 1995; Rasanen et al. 1995; Potter 1997; Doerr 1999).

Historical Biogeography and Adaptive Radiation

To assess historical patterns of biogeographic diversification, we overlaid geographic distributions on the bromeliad phylogeny using MacClade 4.0 (Maddison and Maddison 1992). Geographic ranges of the terminal taxa were divided into recognized biogeographic areas of endemism (Brazilian Shield [including the Atlantic Shield and Phanerozoic deposits near the Rio de la Plata], Guayana Shield, Amazon basin, Andes, Caribbean [including the adjacent littoral of northern South America], Central America, and tropical west Africa). Single species acting as placeholders for large genera (e.g., \textit{Tellandia}, \textit{Vriesea}) were coded as polymorphic for all regions occupied by members of those genera. We used accelerated transformation to minimize the number of apparent convergent gains. Spatial shifts in distribution were then related to the chronology obtained from the analysis of ultrametric trees, and to inferred shifts in ecology and associated adaptations.

We overlaid the epiphytic habit and CAM photosynthetic pathway on the bromeliad phylogeny to assess patterns of evolution in two traits thought to be crucial to the ecological abundance and evolutionary success of bromeliads as a whole (Pittendrigh 1948; Tomlinson 1969; Benzing 1980, 2000). We also overlaid ornithophily (avian pollination) on the entire bromeliad phylogeny, and overlaid several leaf traits apparently related to drought tolerance (internal water storage tissue; lack of differentiation within chlorenchyma; hypodermal sclerenchyma; trichomes with extensive wings; and overlapping trichomes arranged in distinct rows and vertical tiers) on that part of the phylogeny corresponding to the traditional Pitcairnioideae. We obtained data on CAM photosynthesis from Martin (1994); on ornithophily and epiphylism, from Smith and Downs (1974), Galetto and Bernardello (1992), Smith and Till (1998), and Benzing et al. (2000b); and on leaf and trichome anatomy of Pitcairnioideae, from Varadarajan and Gilmartin (1988). Our aim was to relate adaptive shifts to the chronology, ecology, and biogeography of bromeliad diversification, and to determine whether individual traits or suites of traits arose once or many times independently.

RESULTS

Phylogeny

For the bromeliad-centered data set, maximum parsimony resulted in 12 shortest trees of length 1617 steps, and a well-

Table 1. Species included in this study. Nomenclatural authorities were obtained from the International Plant Names Index website (IPNI 2004). Herbarium vouchers indicated in italics; initial citations and garden accessions are shown in roman. SEL = Marie Selby Botanical Garden; StL = Missouri Botanical Garden.
resolved strict consensus (Fig. 1). For these trees, the consistency index (CI) was 0.66 (0.57 excluding autapomorphies = CI'), while the retention index (RI) was 0.82. Overall, 807 nucleotide sites were variable, of which 510 were phylogenetically informative. Within Bromeliaceae alone, 269 sites were variable and 112 were informative.

Sequence variation in *ndhF* strongly supports the monophyly of Bromeliaceae (100% bootstrap value) and resolves eight major clades, arranged in ladderlike fashion (Fig. 1, 2). Earliest divergent is *Brocchinia*, an extraordinary genus of ca. 20 species restricted to wet, extremely infertile habitats of the tepuis and adjacent sand plains of the ancient Guayana Shield (Givnish et al. 1997). *Brocchinia* has undergone an adaptive radiation in mechanisms of nutrient capture unparalleled at the generic level across the angiosperms, including carnivorous species, ant-fed myrmecophytes, tank epiphytes, impounding treelets, N₂-fixers, and terrestrial forms that absorb nutrients primarily through their roots.

*Brocchinia prismatica* is basalmost, consistent with its position based on cpDNA restriction-site data and a more extensive sampling of taxa (Givnish et al. 1997). Monotypic *Ayensua* is embedded within *Brocchinia*, between *B. prismatica* and *B. paniculata* (Fig. 1). The latter is the earliest-divergent member of the Melanacra clade, which is sister to all other *Brocchinia* except *B. prismatica* based on restriction-site data (Givnish et al. 1997). *Ayensua waipanensis* shares a highly unusual, sharply defined abscission zone at the base of each leaf with *Brocchinia*, and is the earliest-divergent member of the Melanacra clade (Givnish et al. 1997).

The second divergent clade of Bromeliaceae is *Lindmania*, a genus of ca. 20 species limited to the tepuis of the Guayana Shield (Holst 1997). The next two clades—the monophyletic subfamily Tillandsioidae (*Catopsis, Glomerocarpus, Guzmania, Tillandsia, Vriesea*) and the xerophytic genus *Hechtia* from Central America and Mexico (Fig. 1)—are part of a hard trichotomy, including the remaining genera of the higher bromeliads. Among this latter group, the fifth major clade of bromeliads includes three taxa restricted to the Guayana Shield—*Brewcaria*, species-rich *Navia*, and the disparate “*Brocchinia*” *serrata*—as well as monotypic *Cottendorfia* from the Brazilian Shield (Fig. 1). Givnish et al. (1997) resolved *Brewcaria reflexa*, *Navia saxicola*, and “*Brocchinia*” *serrata* as close relatives based on cpDNA restriction-site variation; the last species differs from all others now classified as *Brocchinia* in having a superior ovary and spinescent leaves.

The sixth rung of the bromeliad ladder includes four highly xeromorphic genera (*Abromeitiella, Deuterocohnia, Dyckia, Encholirium*), sister to the slightly more mesomorphic *Fosterella* (native to dry valleys at mid elevations in the northern Andes and Central America [Bisch et al. 1997]), and ultimately to the large genus *Pitcairnia*, native to the Amazon basin, northern Andes, Guayana Shield, Central America, and the Caribbean, with a single species (*P. feliciana*) in western South Africa. Finally, as shown by Terry et al. (1997a), the large genus *Puya* (ca. 120 spp.)—centered in the southern Andes but extending northward into Central America and the Guayana Shield—is closest relative of the monophyletic subfamily Bromelioideae. Together, these two groups form the seventh and eighth major clades of bro-
Fig. 1.—Phylogram of one of the 12 most-parsimonious trees based on ndhF sequence variation. Numbers above nodes indicate bootstrap support values. Arrows indicate branches that collapse in the strict consensus of the parsimony trees. Note that in all figures, *Brocchinia serrata* is shown as *Sequencia serrata*, and *Ayensua uaiapanensis* as *Brocchinia uaiapanensis*, reflecting the nomenclatural changes proposed in this paper.

meliads (Fig. 1). The traditional subfamily Pitcairnioideae (highlighted by black bars in Fig. 2) is thus massively paraphyletic, forming the winged-seed matrix from which both plumose-seeded tillandsioids and fleshy-fruited bromelioids emerge, and comprising six of the eight major bromeliad clades.

Reflecting the short branch lengths in the family, bootstrap support values based on ndhF for major clades of bromeliads—and for relationships among those clades—are often lower than those in closely related families of Poales (Fig. 1), or across monocots more generally (Givnish et al. 2006). *Brocchinia* (including *Ayensua*) is strongly supported as being sister to all other bromeliads (97% bootstrap value), while *Lindmania* has moderate support (84%) as being sister to the rest of the family excluding itself and *Brocchinia–Ayensua* (Fig. 1). *Navia, Brewcaria, Cottendorfia*, and “*Brocchinia” serrata* form a strongly supported clade (95%), as do *Puya* (100%), Bromelioidae (89%), and *Puya–Bromelioidae* (99%), as well as *Dyckia–Encholirium* (100%), *Abromeitiella–Deuterocohnia* (99%) and *Guzmania–Tillandsia–Vriesea* among the tillandsioids (97%). Other relationships within the family have weaker support, includ-
Fig. 2.—Ultrametric tree for Bromeliaceae based on cross-verified penalized likelihood, showing inferred chronology of cladogenesis over the past 20 My. Major clades (see Discussion for definitions) are highlighted by brackets; membership of these clades in the three traditional subfamilies is indicated by shaded bars. Hollow bar = Bromelioideae; gray bar = Tillandsioideae; solid bars = Pitcairnioideae. Note the manifold paraphyly of Pitcairnioideae, and monophyly of both Bromelioideae and Tillandsioideae.

Molecular Clocks and Historical Biogeography

The ndhF gene evolves in a somewhat non-clocklike fashion in Bromeliaceae (\(P > 0.053\), \(\chi^2\) test with 33 d.f.), so simple molecular clocks cannot be used to date cladogenetic events within the family (see also Givnish et al. 2004). Based on a PL analysis across monocots, we infer that Bromeliaceae arose 69.5 Mya—coincident with the rise of Typha–Sparagnum, one of the events used to calibrate the monocot tree—and that 50 million years (My) elapsed between the rise of the bromeliad stem group and divergence among the crown group of surviving lineages 19 Mya (Fig. 2). Extant lineages of Brocchinia–Ayensua began to diversify roughly 17 Mya (Fig. 2). Brocchinia arose at low elevations and then evolved adaptations to nutrient poverty (carnivory, ant-fed myrmecophily, \(N_2\) fixation) that depended on acquiring the tank habit and live absorptive trichomes; evolution of these traits was contingent on occupying rainy, humid, extremely nutrient-poor habitats at high elevations on the tepuis (Givnish et al. 1997). Brocchinia's distribution is coextensive with the Guayana Shield, with almost all species occurring on sand or sandstone on the tepuis or sand plains at low elevations; a few species also occur on granite outcrops at the edge of the Shield, or on low sandstone mesetas in southwestern Colombia (Givnish et al. 1997). Lindmania is restricted to the tepuis and arose 16 Mya (Fig. 2).
Fig. 3.—Phylogenetic reconstruction of geographic diversification in bromeliads, based on the modern distributions of terminal taxa, branching topology, and parsimony. Gray branches indicate uncertainty in the reconstruction of ancestral distributions.

The nesting of two lineages endemic to the Guayana Shield—*Brocchinia–Ayensua* and *Lindmania*—at the base of Bromeliaceae implies that the family arose there. This biogeographic scenario is consistent with the geological age of the terrains involved. The initial uplift of the sandstone and quartzite marine deposits to form the tepuis of the Guayana Shield is widely assumed to have coincided with the rifting of the tropical Atlantic; the dissection of individual tepuis from each other via erosion and chemical dissolution is thus likely to have proceeded for the past 90 My (Givnish et al. 1997).

After the origin of *Brocchinia–Ayensua* and *Lindmania* in the Guayana Shield, and a modest amount of speciation associated with them, our biogeographic and chronological reconstructions imply that bromeliads began to expand centripetally into other regions of South and Central America about 15 Mya, based on PL (Fig. 2, 3). This period of initial geographic expansion coincided with the origins of strongly xeromorphic lineages, including *Hechtia* (with heavily armed, succulent leaves and CAM photosynthesis) and Tillandsioideae (many epiphytic, with a large number of species in the *Guzmania–Tillandsia–Vriesea* clade having CAM photosynthesis) (Fig. 2–4). *Hechtia* and the tillandsioids represent the first bromeliad invasions of Neotropical regions outside the Guayana Shield (Fig. 3). Both involve northern South America, with *Hechtia* reaching Central America.
Phylogenetic reconstruction suggests that subfamily Tillandsioideae evolved in the Guayana Shield (Fig. 3), but that inference is probably an artifact of the arbitrary choice of species used to represent Guzmania, Tillandsia, and Vriesea. The latter genera have broad ranges, and are especially diverse in the Andes (Smith and Downs 1977). More important, Glomeropitcairnia is endemic to parts of northern Venezuela and Trinidad immediately adjacent to the Guayana Shield, and some Catopsis species (e.g., C. berthomiana Mez) inhabit the Guayana Shield as part of more extensive ranges (Smith and Downs 1974). Most other tillandsioid genera have ranges overlapping the Guayana Shield, but also occur in other regions and are more diverse outside the Guayana Shield, especially in the Andes. These facts suggest that Tillandsioideae may have originated just beyond the periphery of the Guayana Shield, near the Caribbean littoral. Origen of the species-rich Guzmania–Tillandsia–Vriesea clade—including the most highly specialized, “atmospher-
to Bahia is suggested by *Dyckia*’s range, which abuts *Deu-
terocolonia* in the west and *Encholirium* in the east on the
horn of Brazil (Givnish et al. 2004). Further research is
needed to determine if xeromorphic *Encholirium* is sister to
a monophyletic *Dyckia*, or instead derived from within it.
Divergence between the species representing each of these
genera occurred quite recently, ca. 2.5 Mya; *Abromelitiella*
and *Deuterocolonia* appear to have diverged slightly after
that, at the beginning of the Pleistocene (Fig. 2).

Based on PL, African *P. feliciana* diverged from its Amer-
ican counterparts 10.1 Mya (Fig. 2). These calculations ex-
clude vicariance via continental drift as a possible explana-
tion for the occurrence of *P. feliciana* in Africa, and point
instead to relatively recent long-distance dispersal around 10
Mya.

The lineages that generated *Puya* and subfamily Brome-
lioideae diverged from each other 9.1 Mya, with *Puya*
diversifying mainly along the Andes and the bromelioids aris-
ing in one of several places, including northern South Amer-
ica, before invading the Brazilian Shield about 6 Mya (Fig.
2, 3). Some early-divergent bromelioids (including *Bromelia*
and the pineapple *Ananas*) occur in a diversity of regions,
including seasonal parts of northern South America and Cen-
tral America, but most of the later-divergent genera are en-
demic to seasonal parts of the Brazilian Shield (Smith and
Downs 1977). Many of the latter, despite their fleshy fruits
and potential for long-distance dispersal, have narrow rang-
es, and they probably represent in situ diversification within
the Brazilian Shield. More species of *Puya* (ca. 120 spp.)
need to be sequenced to obtain a better estimate of when
present-day species began to diverge from each other. We
estimate that the small, wide-ranging *P. floccosa* (subgen.
*Puyopsis*) and the gigantic *P. raimondii* (subgen. *Puya*
from the central Andes diverged within the past 600,000 years
(Fig. 2).

Our estimated dates for the history of Bromeliaceae based
on PL are generally consistent with those based on lineage-
specific mutation rates or local molecular clocks (data not
shown), but much more recent than those based on NPRS
(Givnish et al. 2004). The latter produces dates about twice
those inferred using cross-verified PL. Important biases in
the NPRS approach—especially the amplification of minor
differences in branch length in a nearly clocklike tree, and
the effects of low rates of molecular evolution in
*Pitcairnia* vs. flanking clades—are discussed in detail by Givnish et al.
(2004).

**Adaptive Radiation**

CAM photosynthesis arose at least four times in Brome-
liaeae, in *Puyo*–Bromelioidae, Pitcairnioideae minus *Pit-
cairnia* itself, Tillandsioideae, and *Hechtia* (Fig. 4). In each
of these clades, CAM is associated with either arid habitats
or epiphytic microsites in rain and cloud forests. C₃ pho-
tosynthesis is inferred to be the ancestral state. Roughly two-
thirds of all bromeliads are estimated to possess CAM
(Crayn et al. 2000, 2004) and associated leaf succulence.
Together, these traits provide a potent means of reducing
transpiration and enduring intense drought, albeit at the cost
of reduced photosynthetic capacity (Winter and Smith 1996).
Epiphytism also arose at least four times among bromeliads,
in Bromelioidae, Tillandsioideae, and *Brocchinia* (Fig. 5),
as well as *Pitcairnia* (epiphytic taxa not included in our sur-
vey). Epiphytes in *Brocchinia* include *B. tatei* L. B. Sm., a
tank-forming species that impounds rainwater among its
tightly overlapping leaf bases, and is closely related to the
carnivorous *B. reducta* Baker and *B. hechtioides* Mez in the
Reducta clade (Givnish et al. 1997). Almost surely, *Broc-
chinia hitchcockii* L. B. Sm. in the Melanacra clade repre-
sents an additional origin of epiphytism within the genus
(Givnish et al. 1997), and it seems likely that additional or-
igans of epiphytism occur within the three other, much larger
clades that possess epiphytic species (Benzing et al. 2000a).
The ancestral bromeliads apparently evolved at low eleva-
tions in the Guayana Shield on moist, infertile substrates of
sand or sandstone (Givnish et al. 2004).

Ornithophily arose at least twice: in Tillandsioideae and
the common ancestor of Pitcairnioideae–Puyoideae–Brome-
liaeae (Fig. 6). The occurrence of entomophily in *Catopsis*

![Diagram](image-url)
may not reflect a reversal from ornithophily in tillandsioids: Terry et al. (1997b) place this genus sister to the higher (mostly bird-pollinated) tillandsioids using nadhF and a more extensive sampling of tillandsioid genera and species. Hummingbirds (Trochilidae) are the most common avian pollinators (see review by Benzing et al. 2000b). Austral blackbirds (Icteridae) also visit some species of Puya (Smith and Till 1998; Benzing et al. 2000b). Species of Puya sect. Puya have sterile terminal tips on branches of their inflorescences that serve as perches, as well as relatively shallow flower-tubes; as a result, they attract a variety of both perching and hovering species. By contrast, species of Puya sect. Puyopsis have deeper-throated flowers held in more densely congested inflorescences, favoring mainly hovering birds (i.e., hummingbirds) (Baker et al. 1998; Benzing et al. 2000b). Insect pollination—which characterizes all species of Brocchinia and Lindmania, as well as all or most species of Brewcaria, Catopsis, Cottendorfia, Navia, and Fosterella, based on direct observations or inferences from floral syndrome (Benzing et al. 2000b)—is inferred to be the ancestral state. Most high-elevation groups—even cushion plants of Abromeitiella and Deuterocohnia in dry microsites of the high Andes (Galetto and Bernardello 1992)—are pollinated by hummingbirds. Dyckia, with yellow to orange flowers and growing in dry microsites at low to mid elevations, also appears to be hummingbird pollinated (Galetto and Bernardello 1992; P. E. Berry and K. J. Sytsma pers. obs.). Reversion to entomophily occurred in Fosterella, apparently with retention of ornithophily (or another origin) in hummingbird-pollinated F. spectabilis (see Luther 1997). Several lineages in which ornithophily has evolved also possess species pollinated by bees (e.g., Tillandsia multiculis Sted.), moths (Pitcairnia albiflos Herb., Pitcairnia unilateralis L. B. Sm., Tillandsia utriculata L.), and—perhaps most notably—bats (e.g., Pitcairnia palmoides Mez & Sodiro, Puya ferruginea (Ruiz & Pav.) L. B. Sm., Guzmania fosteriana L. B. Sm., Vriesea subgen. Xiphion E. Morren, Tillandsia subgen. Pseudalcan-tarea Mez) (Vogel 1969; Ortiz-Crespo 1973; Gardner 1986; Luther 1993; Sazima et al. 1995; Benzing et al. 2000b; Wendt et al. 2002). More research is needed to determine whether such pollination syndromes have evolved once or many times within individual large genera, or whether certain poorly studied genera (e.g., Connellia, Lindmania, Navia) contain ornithophilous species. It is well established that Encholirium is bat pollinated (Sazima et al. 1989). Varadarajan and Brown (1988) report that Ayensua is also bat pollinated, but this seems quite unlikely, given the minute size of the flowers (comparable to those of entomophilous Brocchinia) and the extremely short stature of the plants. Pitcairnia feliciana of West Africa bears the hallmarks of avian pollination—orange-red flowers, no fragrance, copious nectar production—and has flowers quite similar to those of many hummingbird-pollinated species of Neotropical Pitcairnia; no direct observations of sunbirds pollinating this species have been made as yet, however (Porembski and Barthlott 1999).

Based on the data on leaf and trichome anatomy now available for genera of the traditional Pitcairnioidae (Varadarajan and Gilmartin 1988), several traits associated with life in arid habitats appear to have evolved independently many times, especially in Hechtia, Puya, and members of the Xeric clade (Abromeitiella–Deuterocohnia–Dyckia–Encholirium; Fig. 7). This clade is restricted to dry habitats in southeastern Brazil, northern Argentina, and high elevations in the central Andes (Givnish et al. 2004). Two traits—foliar trichomes arranged in parallel rows, and overlapping substantially in periclinal tiers—occur in all three of these groups. Two additional traits—internal water storage tissue and a lack of differentiation within the chlorenchyma (no palisade vs. spongy mesophyll)—also occur in all three of these groups, but also extend to Fosterella, sister to the Xeric clade. Well-developed wings are present on the foliar trichomes only of Puya and the Xeric clade, and are missing from Hechtia. Finally, hypodermal sclerenchyma is present in Hechtia, Puya, the Xeric clade, Pitcairnia sect. Pepinia Brongn. ex Andra, Ayensua, and certain bromelioids. Thus,
Fig. 7.—Independent origins of leaf and trichome traits associated with life in arid habitats, based on data for genera placed in Pitcairnioideae s.l. only (tillandsioids and bromelioids, shown with dotted branches, were assigned the apomorphic states). Characters and character states (apomorphic state given in parentheses): 1 = foliar trichomes arranged in parallel rows (vs. irregular pattern); 2 = margins of foliar trichomes overlap extensively in periclinal tiers (vs. little or no overlap); 3 = internal water storage tissue present (vs. only adaxial water storage tissue present); 4 = chlorenchyma undifferentiated (vs. palisade and spongy mesophyll present); 5 = marginal wings of foliar trichomes well-developed (vs. scarcely developed or absent); and 6 = hypodermal sclerenchyma present (vs. absent). Note the apparent pattern of concerted convergence involving independent origins of a suite of drought-adapted characters in Puya, the Xeric clade, and Hechtia.

**Xeromorphic leaf traits**

1. Well-developed wings on foliar trichomes
2. Trichomes in parallel rows
3. Trichomes in periclinal tiers
4. Hypodermal sclerenchyma
5. Internal water-storage tissue
6. Undifferentiated chlorenchyma

**Phylogeny and Systematic Implications**

Our findings regarding relationships within Bromeliaceae are largely consistent with the analyses of Terry et al. (1997a), Crayn et al. (2000, 2004), Horres et al. (2000), and Reinert et al. (2003), and provide the first comprehensive and well-resolved view of relationships across all major bromeliad lineages. As expected given their joint basis on ndhF sequences, our results and those of Terry et al. (1997a) coincide for the taxa included in both studies. Our novel results include (1) the embedding of Ayensua within Brocchinioideae at the base of the family, (2) the placement of the tepui endemic...
ic Lindmania as the next-divergent clade, (3) the hard polytomy formed by Tillandsioidae, Hechtia, and all remaining bromeliads, (4) a new clade forming the next branch above this polytomy, including Navia, Brewcariaceae, Cottendorfa, and “Brocchinia” serrata, (5) the placement of Abromeitiella and Deuterocohnia sister to each other, and together sister to Dyckia and Encholirium, and (6) confirmation of Fosterella as the sister group to this clade of four highly xeromorphic genera. The two species of Pitcairnia subgen. Pepinia (P. corallina, P. hirtiz) are sister to each other in our analysis, but monophyly of subgen. Pepinia—to say nothing of Pitcairnia subgen. Pitcairnia—is not supported by a more comprehensive sampling of the genus and matK sequence variation (Reinert et al. 2003). Most important, our ndhF phylogeny demonstrates that (7) the traditional subfamily Pitcairnioideae is paraphyletic and that Tillandsioidae and Bromelioidae both evolved from within it. The phylogeny of Horres et al. (2000) is less well resolved than either of the ndhF trees, but is consistent with ours in placing single species of Brocchinia and Ayensua as sister to each other, and in placing this group, Hechtia, and all other bromeliads in an unresolved trichotomy. The phylogeny of Crayn et al. (2004), although less well resolved than that of Horres et al. (2000), is also consistent with our findings. Taken together, these results clearly call for two nomenclatural changes involving Brocchinia and Ayensua, the description of four new subfamilies of Bromeliaceae, and the recircumscription of Pitcairnioideae and Navisieae, as described next.

1. Ayensua.—The position of Ayensua within Brocchinia is supported not only by our ndhF data and the sharing of a highly unusual leaf abscission zone in Ayensua and B. maguirei (see above), but also by unpublished rbcL-atpB cpDNA spacer sequences (K. G. Karol, T. J. Givnish, and K. J. Sytsma in prep.). Ayensua and Brocchinia share a partly to wholly inferior ovary; minute, regular, white or whitish petals; cochlear sepal (the two posterior overlapping margins of the anterior); and stoma with wedge- or bulb-shaped thickening at apical junctures of the leaf cells (Smith and Downs 1974; Robinson and Taylor 1999). Based on the balance of molecular and morphological evidence, we are therefore sinking Ayensua into Brocchinia:

Brocchinia uaiipanensis (Maguire) Givnish, comb. nov.

This species has had a curious history, having been first described as a member of one genus of Velloziaceae by Bassett Maguire, then transferred to another genus in the same family by Lyman Smith, then the expert nonpareil on Bromeliaceae (!), and then finally transferred to Bromeliaceae by Smith (1969) upon the advice of Ayensua (1969). Its leaves are substantially thicker and more awl-like than those of other Brocchinia species; it has a sparsely branched habit with persistent, sheathing leaf bases and adventitious roots that run back down the stem under those leaf bases. Overall, its vegetative aspect is indeed similar to some Velloziaceae of order Pandanales. However, Brocchinia maguirei also has persistent leaf bases, and several Brocchinia species (e.g., B. micrantha Baker) have adventitious roots that interpenetrate the stem cortex. The adaptive significance of B. uaiipanensis’ growth form is unclear. It is restricted to Auyan-tepui and nearby Uaipan-tepui in southeastern Venezuela, and often grows in sparsely covered sites over fractured sandstone, atop windswept brinks and along streams (T. J. Givnish pers. obs.).

Varadarajan and Gilmartin (1988) used a cladistic analysis of morphological data to argue that Brocchinia lies at the base of the subfamily Pitcairnioideae, and placed it as the sole genus in a new tribe Brocchinieae. They contended that Ayensua should be placed in a new tribe Pitcairnieae with Fosterella, Pitcairnia, Cottendorfa (from which Lindmania was subsequently segregated), Connellia, and Steyerbromeiae. They also erected tribe Puyae for the xeromorphic genera Abromeitiella, Deuterocohnia, Dyckia, Encholirium, Hechtia, Brewcariaceae, and Puya. None of these proposed entities—adopted by Smith and Till (1998)—is supported by our molecular phylogeny (Fig. 1), so we reject each of these tribal names.

2. New bromeliad subfamilies.—Our ndhF phylogeny does indicate that the existing subfamilial classification is outdated; although Tillandsioidae and Bromeloidae are monophyletic and can be maintained, Pitcairnioideae are paraphyletic. Given the ladderlike branching pattern in the ndhF bromeliad phylogeny, subfamily Pitcairnioideae must be recircumscribed and at least five new subfamilies erected if all resulting entities are to be monophyletic and the morphologically distinctive Bromelioideae and Tillandsioidae maintained.

We therefore propose the following four new subfamilies of Bromeliaceae, and recircumscribe two others:

Fructibus capsularibus, semenibus bicaudato-appendiculatis; petals minutis, regularibus, liberos; sepals coelarebus, duo adaxials abaxialis superantibus; ovario infero vel partim infero; infloroscencia racemosa paniculata capitatae; foliis integris persaepe chlorenchyma. Capsular fruits, seeds bicaudate appended; petals minute, regular, free; sepals coelare, with the two adaxial overlapping the abaxial; ovary partly to wholly inferior; infloroscencia racemose, paniculate, or capitate; leaves entire, almost always with stellate chlorenchyma.

Included genus: Brocchinia

Lindmanioidae Givnish, subfam. nov.—TYPE: Lindmania Mez.

Fructibus capsularibus, semenibus bicaudato-appendiculatis; anthers subbasifixis equitantibus, erectis, crassis, filamentos liberos; petals nudi; sepals convolutis; stigmatibus erectis, rectis; floribus pedicellatis; foliis integris vel spinosis-denticulis; sine chlorenchyma. Capsular fruits; seeds bicaudate appended; anthers subbasifix equitant, straight, stout; filaments free; sepals convolute; petals naked; stigmas erect, straight; flowers pedi-
icellate; leaves entire or toothed/spinose; stellate chlorenchyma absent.

Included genera: Connellia, Lindmania

Hechtioideae Givnish, subfam. nov.—TYPE: Hechtila Klotzsch.

Fructibus capsularibus, seminibus alatis vel fere nudis; floribus dioeciosis; foliis succulentis, spinoso raro integris; sine chlorenchymali stellato.

Capsular fruits; seeds winged to almost naked; flowers dioecious; leaves succulent, spinose or rarely entire; stellate chlorenchyma absent.

Included genus: Hechtia

Puyoideae Givnish, subfam. nov.—TYPE: Puya Molina.

Fructibus capsularibus, seminibus circumferentio-alatis; lamanis petalorum arcte torvisis post anthesin; sepalis convolutis.

Capsular fruits; seeds circumferentially winged; petal blades tightly spiralled after anthesis, broad and distinct from claw; sepal convolute.

Included genus: Puya

Navioideae, descr. emend.

Capsular fruits; seeds winged to naked; petals minute; sepals coheal, with the two adaxial overlapping the abaxial; stellate chlorenchyma absent; water storage tissue peripheral only, trichomes irregularly arranged with little overlap, epidermis smooth, hypodermal sclerenchyma absent; stellate chlorenchyma absent; leaves entire, serrulate, or spinose, but not succulent; inflorescence paniculate to capitulate.

Included genera: Brewcaria, Cottendorfia, Navia, Sequenaria, Steyerbromelia

Pitcairnioideae, descr. emend.

Capsular fruits; seeds winged; petal blades remaining free after anthesis (or, if slightly coiled, then not clawed); petals large and conspicuous or, if minute, then sepals imbricate and anthers basifixed, linear.

Included genera: Abromeitiella, Deuterocohnia, Dyckia, Enchlorium, Fosterella, Pitcairnia

We offer the following key to identify bromeliads to subfamily:

KEY TO BROMELIAD SUBFAMILIES

1. Fruits indehiscent, baccate ........................................ Bromelioidae
   − Fruits dehiscent, capsular ........................................ 2
   2. Seeds plumose-appendaged .............................................. Tillandsioidae
      − Seeds convolute ...................................................... 3
     3. Flowers dioecious, plants of Central America ... Hechtioideae
        − Flowers perfect, or rarely monoecious or polygamioecious, or dioecious and plants of the Brazilian Shield ........ 4
      4. Petal blades showy, tightly spiralled after anthesis, broad and distinct from claws ........................................ Puyoideae
         − Petal blades remaining free after anthesis, or if slightly coiled, then not clawed ........................................ 5
     5. Petals large and conspicuous or, if minute, then sepals imbricate and anthers basifixed, linear ........... Pitcairnioideae
        − Petals minute and sepals cochlear, or petals and bracts various and sepals convolute ........................................ 6
     6. Sepals convolute ............................................................ Lindmariantodeae
        − Petals minute and sepals cochlear ...................................... 7
     7. Leaves entire, stellate chlorenchyma abundant .......................................................... Brocchinioideae
        − Leaves toothed, stellate chlorenchyma absent .............. Navioideae

The newly defined Brocchinioideae correspond to Brocchinia as recircumscribed in this paper. Varadarajan and Gil- martin (1988) proposed segregating Brocchinia into its own tribe within Pitcairnioideae, but failed to recognize its close relationship to Ayensua. Smith and Till (1998) adopted the same view and formally recognized Brocchinieae within the pitcairnioids. Terry et al. (1997a) informally suggested that, based on additional data, Brocchinia might be best segregated in its own subfamily, and R. Thorne and J. Reveal now use “Brocchinioideae” on their websites (http://www.csd1.tamu.edu/FLORA/newgate/thorcomm.htm and http://www.life.umd.edu/emeritus/revel/pbto/pb450/zing.html), without citing an authority or formal description. The trnL intron data of Horres et al. (2000) support a close relationship between single species of Brocchini-a and Ayensua, consistent with our results—based on a more comprehensive and critical sampling of taxa—which clearly place Ayensua within Brocchinia.

We have drawn Lindmariantodeae so as to permit inclusion of Connellia. This genus, restricted to the tepuis of southeastern Venezuela and adjacent Guyana, differs from Lindmania mainly in having larger and more brightly colored petals and subbasifixed vs. equitant anthers; both genera appear to be clearly related based on morphology (Holst 1997). The striking difference in the phylogenetic positions of Lindmania and Cottendorfia supports the decision to segregate taxa that had all been lumped into Cottendorfia (Smith 1986; Holst 1997). The position of Hechtia just above Lindmania and near Tillandsioidae (Fig. 3) is, however, surprising. Hechtia shares at least five derived anatomical leaf characteristics with Abromeitiella, Deuterocohnia, Dyckia, and Enchlorium (Varadarajan and Gilmartin 1988), and Robinson and Taylor (1999) placed these genera in a new tribe Dyckieae based on these traits. However, these traits—including adaxial water storage tissue, a lack of differentiation within the chlorenchyma, overlapping trichomes, stomata in sunken pits or rows, grooved epidermis—all appear to be adaptations to extreme drought, and are associated with thick, succulent leaves with CAM photosynthesis that are (at least in the lowland forms) heavily armed. Central American Hechtia thus appears to represent an extraordinary case of concerted convergence with Dyckia and Enchlorium, and to a lesser degree with Abromeitiella and Deuterocohnia, all from central South America. Ranker et al. (1990) found one restriction-site mutation that joined single species representing Dyckia and Hechtia, but the very small number of characters (19) and bromeliad taxa (10) included in that study, as well as its failure to place Glomeropitcairnia in a monophyletic Tillandsioidae, argue against giving it much weight. Crayn et al. (2000) found that Hechtia segregated from all other pitcairnioids genera or groups of genera, including (Abromeitiella)–Deuterocohnia–Dyckia–Enchloriium. Distinction between the latter clade and Hechtia had a decay value of at least 7 in the analysis by Crayn et al. (2000), consistent with our finding that these two groups appear at different ends of the bromeliad ladder. Interesting-
ly, however, a second group of *Deuterocohnia* species did not group with those in the clade with *Dyckia* and *Encholirium*, forming part of the large, nine-way polytomy.

Navioidae are recircumscribed here based on *ndhF* sequence variation. The close relationship of *Brewcaria* and *Navia* is suggested by their shared possession of naked seeds; most species of *Brewcaria* were originally placed in *Navia* until Holst (1997) reclassified those with spicate or paniculate inflorescences. *Steyerbromelia* is quite similar to *Brewcaria*, but has winged seeds. A close relationship between *Brewcaria*, *Navia*, and *Brocchinia* serrata (see below) is strongly supported by a cpDNA restriction-site study that analyzed the same species (and more distantly related *Lindmania longipes*) as part of phylogenetic analysis of *Brocchinia* (Givnish et al. 1997). That study indicated the same pattern of relationships among these three taxa as found in this paper. *Cottendorfia* shares cochlear sepals with *Brewcaria*, *Navia*, *Steyerbromelia*, and *Brocchinia* serrata, as well as a few other genera formerly placed in Pitcairnioideae. The association of *Cottendorfia* with *Navia*, among other genera, in Navioidae is supported by the sister relationship of *Cottendorfia floridana* with *Navia phelpsioides* based on *marK* sequence variation (Crayn et al. 2000, 2004; Reinert et al. 2003). However, these studies also place *Navia igneosicola* sister to almost all species of *Pitcairnia* (including subgen. *Pepinia*) in a separate clade, with a decay value of 1. *Navia* is a large and complex genus recently revised by Holst (1997), who found the previous concept of the group overly broad and segregated all of the noncapitate species into *Brewcaria*, *Steyerbromelia*, and *Brocchinia*. The validity of these shifts has yet to be tested using molecular data, and it may well be that some species remaining within *Navia* remain outside a monophyletic core. If this later proves to be the case, the naming of this broader group will need to be revisited. *Navia igneosicola* differs from several tepui *Navia* in having wider leaves and pigmentation on leaf bases near the inflorescence that shows a more irregular transition to the green of the distal leaf areas. It may simply be an early divergent species of *Pitcairnia* with a condensed, capitate inflorescence. We note that *Pitcairnia leopoldii* (W. Till & S. Till) B. K. Holst—again with a capitate inflorescence—was initially considered a *Navia* due to habit and ovules similar to those of *Navia*; more detailed study showed that it had petal appendages and zygomorphic flowers, so it was described instead as a *Pitcairnia* (Oliva-Esteve 2002). Other *Pitcairnia* may yet lie unrecognized in *Navia*. The genus *Navia* was recognized as a monotypic subfamily by Harms in 1929, but he promptly sunk it as a monotypic tribe of Pitcairnioideae (Harms 1930). That subfamily was not accepted by later specialists, and this is the first time a broader Navioidae has been proposed.

Our recircumscription of Pitcairnioideae corresponds roughly to that recommended by Terry et al. (1997a), but encompasses genera not included in their study. As recircumscribed, Pitcairnioideae now contain *Abrometilla*, *Deuterocohnia*, *Dyckia*, *Encholirium*, *Fosterella*, and *Pitcairnia*. We believe it is better to recognize Puyoideae separate from Bromelioideae, rather than sinking the former into the latter as recommended informally by Terry et al. (1997a), given the highly distinctive set of phenotypic synapomorphies distinguishing each of these groups from the other. Our phylogeny supports the monophyly of *Pitcairnia* as sampled to date, with *Pitcairnia feliciana* basalmost (Fig. 1). However, our sampling fails to represent a substantial amount of the phenotypic diversity within *Pitcairnia*, including putative Neotropical relatives of *Pitcairnia feliciana*. Such relatives might include *P. fuertesii* Mez from the Caribbean or *P. pungens* Kunth from Ecuador and Peru (Harms and Mildbraed 1938), or certain rock-dwelling species from eastern Brazil, including *P. glaciovii* Baker (Porembski and Barthlott 1999; Benzing 2000); no detailed argument for any of these possibilities has yet been offered. Porembski and Barthlott (1999) assert that *P. feliciana* differs from all other *Pitcairnia* species examined (still very few in this large genus) in several traits: ligula with two toothlike appendages, unlike all other pitcairnioids surveyed; stigma lobes with papillae unlike any other *Pitcairnia* surveyed; seeds with testa cells that have perforated outer pericinal walls (this last trait otherwise known only from certain *Puya*). Resolution of relationships within *Pitcairnia* will require sequencing many more species within the genus. Crayn et al. (2004) found that the eleven species of *Pitcairnia* they sequenced for *marK* and *rps*16 formed two distinct clades.

It is interesting to note that *Pitcairnia* and *Puya*—each the basalmost genus in two large clades that are sister to each other—share several traits (e.g., zygomorphic flowers associated with avian pollination, and several xeromorphic features of leaf morphology and anatomy) and were once thought to be closely related to each other (e.g., see Smith and Downs 1974). Their similarities thus appear, based on phylogenetic reconstruction based on molecular data, to represent plesiomorphies (i.e., shared ancestral characters) rather than synapomorphies.

We did not sample all genera of Bromeliaceae in this study, but believe there are no “surprises” based on excluded taxa that would alter the proposed system of eight subfamilies. The only genera of traditional Pitcairnioideae not sampled—*Connellia* and *Steyerbromelia*—appear, based on morphology, to be very closely related to *Lindmania* and to *Brewcaria* and *Navia*, respectively. All tillandsioid and bromeliioid genera not included in our analysis but studied by Terry et al. (1997a, b) were also placed in monophyletic subfamilies *Tillandsioidae* and *Bromelioideae*, based on *ndhF* sequence variation and a more restricted sampling of traditional Pitcairnioideae.

Although *ndhF* sequences provide a phylogeny that is nearly fully resolved, it must be recognized that only a few synapomorphies support some of the nodes along the “spine” of the tree, with relatively low bootstrap support (<50%) for some clades, including Pitcairnioideae exclusive of *Pitcairnia*, *Pitcairnia* itself, and Navioidae—Puyoideae–Bromelioideae (Fig. 1). A multigene analysis, drawing on data for several cpDNA segments, is now clearly needed to confirm the results presented here. However, our confidence in the systematic arrangement presented here is bolstered by the fact that analyses based on other single cpDNA segments (Terry et al. 1997a, b; Crayn et al. 2000; Horres et al. 2000; Reinert et al. 2003) have already produced results consistent with our phylogeny.

3. *Brocchinia serrata*—As noted above, morphology and two lines of molecular evidence place this taxon in Navi-
Sequencia Givnish, gen. nov.—TYPE: Brocchinia serrata L. B. Sm.

Caule tortuoso-prostrato, lignoso; foliis rosulatis ad 1.8 m longis, laminis linearioblongis, longe caudato-acuminatis, basi spinis atris curvatis, alibi serrulatis; inflorescentia ampulliforme paniculata; floribus reflexis, perfectis, ovario ad ⅔ supero; sepals succulentis, imbricatis, dense lepidotis; petals regulares, inappendiculati; antheris libiris, basi falcata, rectis; filamentis libiris; capsulis septicidalis loculicidales in seminibus bicaudatis.

Leaves linear, caudate-acuminate, to roughly 1.8 m long, with dark curved spines near the base and serrulate toward the tip, and arranged in a rosette about a twisted, prostrate stem. Inflorescence amply paniculate; flowers perfect; ovary roughly ⅔ superior; sepals cochleate/imbricate, densely lepidotis; petals regular, unappended; filaments free; anthers basifixis, stout, straight; capsules septicidal and loculicidal; seeds bicaudate-appended.

Sequencia serrata (L. B. Sm.) Givnish, comb. nov. Basionym: Brocchinia serrata L. B. Sm., Caldasia 1(4): 14, Fig. 2 (1942).

Leaf characteristics and habit differentiate Sequencia from several pitcairniod genera (including Brocchinia), but emphasize its similarity to Brewcaria and Cottendorfia; possession of panicles distinguishes it from Navia. Perfect flowers separate Sequencia from closely related Cottendorfia, as well as Dyckia and Hechitania. An ovary that is two-thirds superior distinguishes it from most pitcairniod genera. Sepal and petal characteristics separate Sequencia from many genera, most importantly Steyerbromelia. The dual form of dehiscence is unknown in Bromeliaceae except Deuterocohnia (see Smith and Downs 1974).

The generic name Sequencia reflects its recognition based on DNA sequence (and restriction-site) characteristics. This monotypic genus is known only from low sandstone mesetas (Cerro de Circasia, Cerro Yapobodó, Cerro de Cahenda) in Vaupés, Colombia. Like many bromeliad genera (see Smith and Downs 1974, 1977, 1979), Sequencia cannot be defined by any single character state that it alone possesses, but rather by a suite of character states that individually can be found in other pitcairniods. Given the apparently slow rate of evolution in bromeliads (Gaut et al. 1992), perhaps reflecting long generation times due to slow growth under short supplies of water and/or nutrients, and the paraphyly of several bromeliad genera defined by single characters (e.g., see Terry et al. 1997b; Horres et al. 2000), generic definitions based on character combinations—while not “cladistically correct”—may be necessary, if not indeed expected. Note that subfamilies Navioidae and Pitcairnioideae, as recircumscribed here, lack single unconditional synapomorphies and are also defined based on character combinations. Detailed molecular studies of relationships within Tillandsioideae have shown that some genera as traditionally defined by one or two characters (e.g., Tillandsia, Vriesea) are, in fact, paraphyletic (Terry et al. 1997b), Associations among the limited set of traits used to define genera in Bromelioidae are even more combinatorial in nature (Smith and Downs 1979), and molecular phylogenetic investigations on relationships and generic circumscriptions within this recently evolved subfamily are now underway (T. Evans and G. Brown pers. comm.).

Historical Biogeography

Our findings demonstrate that Bromeliaceae arose in the Guayana Shield in northern South America, spread centrifugally in the New World from there, and reached tropical West Africa via long-distance dispersal relatively recently—around 10 Mya if we use calculations based on cross-verified PTL. Our evolutionary chronology implies that the modern lineages of bromelioids only began to diverge from each other roughly 19 Mya, with invasions of drier peripheral areas in Central America (Hechitania) and northern South America (Tillandsioideae) beginning 15 Mya. The northern Andes and Central America most likely were invaded independently by at least three major lineages: the higher tillandsiosids (Guzmania, Tillandsia, Vriesea) beginning 12.7 Mya; Fosterella, beginning about 11.5 Mya, and (throughout the Andes) Puya, beginning about 9.1 Mya (Fig. 2; all calculations based on stem groups). Given the low density of taxon sampling at this point, we cannot determine whether any of these lineages invaded the Andes multiple times. Some additional groups (e.g., some Pitcairnia, various bromelioid genera) have also colonized the Andes independently, but we do not have adequate taxon sampling to estimate the timing and/or numbers of such events. The Brazilian Shield was colonized at least three times: by Cottendorfia from the Guayana Shield, ca. 10.2 Mya; by Dyckia–Encholirium from the central Andes, ca. 8.1 Mya; and by the higher Bromelioidae, 5.7 Mya (Fig. 2, 3). Individual species of other diverse groups (e.g., Gazmania–Tillandsia–Vriesea) have doubtless invaded this area independently as well. Most of the current diversity of bromelioids involves lineages that have appeared only in the past 15 My, including Tillandsioideae, Bromelioidae, and as well as the remaining large genera Pitcairnia, Navia, Dyckia, Hechitania, and (perhaps quite recently, at least for modern lineages) Puya. The 50–My period between the rise of Bromeliaceae and the divergence of modern lineages from one another implies that much extinction occurred over the intervening period, and suggests an obvious basis for the morphologically isolated position of the family. The differentiation of most bromeliad genera from each other outside Bromelioidae within a narrow window of about 7 My (see Fig. 2) may help account for the frequent confusion regarding relationships within the family in the past. An alternative analysis of the data presented here, using maximum likelihood and a slightly different set of outgroup taxa, resulted in a chronogram very similar to that presented here (Givnish et al. 2004).

Our phylogeny confirms, in many ways, the traditional view that bromelioids and tillandsiosids arose from within the pitcairniods (Schimper 1888; Mez 1904; Pittendrigh 1948; Tomlinson 1969; Smith and Downs 1974; Benzing et al. 1985; Smith 1989; Benzing 1990). Terry et al. (1997a)
reached a similar conclusion, but had a different impression of the proximity of bromelioids and tillandsioids and the seeming isolation of *Brocchinia* as a result of not having sampled two of the eight major clades of Bromeliaceae, and undersampling two others. Terry et al. (1997a) also concluded—based on the results of Ranker et al. (1990) and their own belief that *Encholirium* and *Hechtia* were essentially interchangeable—that *Hechtia* was closely allied to *Dyckia*, *Encholirium*, *Abromeitiella*, and *Deuterocohnia*, rather than representing a convergent lineage much closer to the base of Bromeliaceae. The phylogenetic treatment of the “adaptive radiation” of Bromeliaceae by Benzing et al. (2000a) based on the findings of Terry et al. (1997a) brings an impressive amount of ecological and physiological data to bear, but in one important sense was premature: too many groups, with crucial biogeographic distributions and physiological and morphological adaptations, were not included. Contrary to previous claims by Varadarajan and Gilmartin (1988) and Benzing et al. (2000a), until now there has been no phylogenetic evidence based on relationships within Bromeliaceae that the family arose in the Guayana Shield; the distribution there of earliest-divergent *Brocchinia* might have simply been an autapomorphy. Givnish et al. (1999) inferred that bromeliads arose in the Guayana Shield based on an analysis of *rbcL* sequence variation showing an apparent sister relationship between Bromeliaceae and Rapateaceae; the latter clearly originated in the Guayana Shield and remains mostly endemic to that region (Givnish et al. 2000). However, more powerful molecular evidence based on an analysis of *rbcL*, *atpB*, and 18S sequences (Chase et al. 2000), *ndhF* sequence variation (Givnish et al. 2006), a 7-gene analysis (Chase et al. 2006), and a 17-gene analysis (Graham et al. 2006) indicates that Bromeliaceae and Rapateaceae occupy adjacent rungs at the base of order Poales instead of being sister to each other.

The classical hypotheses that bromelioids and tillandsioids emerged from a pitcairnioid ancestor were based not on phylogenetic analysis, but on noting that epiphytes—a highly specialized growth form, involving many adaptations for life without contact with the soil—were far more numerous outside the pitcairnioids. No early writer suggested that *Brocchinia* or *Lindmania* lay at the base of the family, or that pitcairnioids were not a monophyletic, natural group. Smith (1934) suggested that *Puya* represented something close to the “‘ur-bromeliad’”, but molecular data show that *Puya* arose quite recently; given its sister relationship to Bromeliaceae, perhaps *Puya* should now be seen instead as the “‘ur-bromelioid’”! Smith’s (1934) proposal that Rapateaceae evolved from within Bromeliaceae via *Navia* is manifestly wrong (Terry et al. 1997a; Givnish et al. 1999, 2000; Givnish et al. 2006).

The conclusion that *Pitcairnia feliciana* represents the outcome of long-distance dispersal from South America to Africa no earlier than 10.1 Ma accords with our earlier finding that *Maschalocepalus dinklagei* of Rapateaceae is also the product of recent (ca. 6 Ma) long-distance dispersal, not ancient vicariance (Givnish et al. 2000, 2004). Recent colonization may help to explain the lack of African speciation in both groups. Historical cycles of aridity (Goldblatt 1993; Querouil et al. 2003) may also have played a role, given that neither Rapateaceae nor *Pitcairnia* are especially drought tolerant. The African endemics of both families occupy nearby ranges: *Maschalocepalus* in savannas and forests on wet sand from Sierra Leone to Côte d’Ivoire; *Pitcairnia feliciana* on sandstone outcrops of the Fouta Djalon massif in Guinea just to the northwest (Porembski and Barthlott 1999; Givnish et al. 2000). The Guinean Mountains retained a wet climate through the Pleistocene and appear to have served as a refugium for wet-climate taxa (Jahns et al. 1998; Dupont et al. 2000). Both Rapateaceae and Bromeliaceae are also likely to be favored by infertile soils, given the origin and continued abundance of both groups in the Guayana Shield. Thus, vicariance of habitat, via rafting of sandstone deposits to either side of the rifting Atlantic, may have played an important role in the disjunct distribution of rapateads and bromeliads, even if the plants themselves colonized Africa much later via long-distance dispersal (Givnish et al. 2004). There are roughly ten other angiosperm families with amphiatlantic distributions (Thorne 1972, 1973); the use of fossil-calibrated molecular clocks also shows that relatively recent, long-distance dispersal probably accounts for this pattern in Melastomataceae (Renner and Meyer 2001) and Vochysiaceae (Sytsma et al. 2004) as well, although the dispersal events also appear to have occurred sometime earlier than in Bromeliaceae.

### Adaptive Radiation and Synthesis

Our data show that CAM photosynthesis and associated leaf succulence arose independently from C₃ ancestors in four different lineages, associated with the invasion of arid habitats (deserts, semi-deserts, and high-elevation grasslands and scrub) or epiphytic perches in rain and cloud forests (Fig. 3). CAM and leaf succulence reduce transpiration at the cost of reduced photosynthetic capacity, and are widely considered adaptations to drought (Winter and Smith 1996). Two of the four lineages in which CAM evolved—Tillandsioideae and *Puya*—Bromelioidae—are identical to, or contain, two of the three lineages (*Brocchinia*, Tillandsioideae, higher Bromelioidae) in which epiphytism also evolved. Crayn et al. (2004) largely agree with these inferences, but recognize only three origins of CAM (and only three, somewhat separate origins of epiphytism), based on a somewhat less resolved phylogeny. Givnish et al. (2004) use the phylogeny presented here, together with elevational data on present-day taxa, to infer that the family Bromeliaceae arose at low elevations (<500 m) in the Guayana Shield. With the results presented here, this implies that the ancestral bromeliad had a terrestrial habit and the C₃ photosynthetic pathway, and was adapted to moist lowland conditions on infertile sands or sandstones in the Guayana Shield.

Most tillandsioids and bromelioids have leaf scales (trichomes) that absorb water and nutrients and facilitate life as an epiphyte (McWilliams 1974; Benzing 1980, 2000; Smith 1989). In many tillandsioids, these trichomes have dead cap cells that fill with water after rainstorms, allowing live cells at the base of the trichome to absorb water and nutrients. After the leaf surface dries, the dead cap cells drain and a vapor trap inside them prevents much loss of water from the live, absorptive cells to the open atmosphere. Tillandsioid trichomes thus form an elegant system for the one-way movement of water and nutrients, much like the corky ve-
lumen on the roots of epiphytic orchids; both ensure that epiphytes don’t “bleed” water from the very organs that allow them to absorb it in the first place (Benzing 1980, 2000). Some tillandsioids, the so-called “atmospherics” like Spanish moss (Tillandsia usneoides L.), are highly specialized and depend almost exclusively on trichomes for their water and nutrient supplies. These trichomes so densely cover the leaves that they reduce light absorption and subsequent transpiration, but can interfere with C_3 photosynthesis when their wet caps are filled with water and cover the leaf surface, as they often are under rain- and cloud-forest conditions. Under these circumstances, CAM photosynthesis can provide a photosynthetic advantage by recycling CO_2 when gas exchange with the external atmosphere is blocked (Pierce et al. 2002). This new physiological insight may help account for the occurrence of bromelioids in many wet (and often shaded) epiphytic microsites, which had previously been thought paradoxical (e.g., see Benzing 2000). Many bromelioids and tillandsioids have an alternative tank habit, in which rainwater is impounded among closely overlapping leaf bases, with water and nutrients being absorbed more slowly.

Absorptive trichomes, and at least two instances of the tank habit, evolved first in Brocchinia, sister to all other Bromeliaceae, apparently as adaptations for nutrient absorption in rainy, humid, and extremely mineral-poor environments atop the tepuis (Givnish et al. 1997). However, trichomes in Brocchinia retain live cap cells (Givnish et al. 1984, 1997; Owen et al. 1988) and hence do not provide the one-way system for water uptake—and the adaptations for life in drier circumstances, including epiphytism outside the most humid cloud forests—that tillandsioid-style trichomes can provide. Once such trichomes, or the CAM photosynthetic pathway, did evolve, a wide range of dry habitats and epiphytic perches became available, which should have stimulated a great expansion in the diversity of bromeliads and the habitats they were able to occupy. Such a shift appears to have first occurred about 15 Mya, with the accelerated rate of appearance of bromeliad genera with the arrival of Hecithia (with CAM photosynthesis), Tillandsioideae (with many species having absorptive trichomes, tank or atmospheric habits, and/or CAM), and the remaining higher bromeliads (with CAM evolving independently later in Pitaclairnioideae s.s. and in Puya-Bromeliolaeae, 9.1–11.9 Mya). The appearance of these traits largely coincides with the centripetal movement of bromeliads from the hyperhumid highlands of the Guayana Shield into drier and more seasonal regions nearby, suggesting a strong (and, quite possibly, causal) link between physiological evolution and historical biogeography. The sensitivity of the absorptive trichome of Brocchinia may have helped restrict them to the wet, highly humid uplands and highlands of the Guayana Shield. Once the barriers to dispersal posed by aridity were spanned, bromeliads could spread widely, and invade and dominate the epiphytic adaptive zone in the New World. They have also become the dominant (or only!) perennials in some extremely arid communities, including parts of the Atacama Desert (Rundel and Dillon 1998) and sunbaked granitic outcrops of the Brazilian Shield (McWilliams 1974; Kessler 2002a, b).

The closely related family Rapateaceae has not evolved similar adaptations to drought or epiphytism (except in Epidryos Maguire, which occurs only in humid cloud forests in the Guayana Shield, Panama, and Ecuador) and so have remained much more tightly corralled within the Guayana Shield and Amazon basin (Givnish et al. 2004).

This intimate interplay between bromeliad phylogeny, ecology, physiology, and biogeography on the one hand, and Earth history on the other, could only have been recognized and studied after a calibrated molecular phylogeny for the family was produced. Better calibrated, better supported phylogenies that embrace a wider range of taxa and ecological specializations within and among genera are now needed. An obvious next strategy to pursue would be to sequence a wide range of species chosen by the research community for all of cpDNA regions—ndhF, matK, trnL–trnF region, rps16, rbcL–atpB spacer—upon which individual research groups have focused their energies hitherto. We note that, while cross-verified PL, Langley-Fitch molecular clocks, and lineage-specific rates of molecular evolution all yield quite similar dates for events in the history of Bromeliaceae, NPRS produces dates for all events (except the family’s origin) that are roughly twice as old as those produced by the other techniques. Together, both sets of calculations yield estimates of the massive, centripetal movement of the family outside the Guayana Shield—and simultaneous evolution of CAM, epiphytism, and numerous leaf and trichome traits adapted to drought—which straddle the estimated time of uplift of the central and northern Andes, shift of the Amazon to its present course, and ecological separation of the Guayana and Brazilian Shields roughly 20 Mya. As our knowledge of the pattern and tempo of differentiation within monocots continues to grow, it will be important to determine whether the “bromeliad revolution” occurred at the same time as these crucial events, or—as our current calculations indicate—several million years later.

Molecular phylogenies for Bromeliaceae cast light on a classic question regarding the evolution of epiphytism. Schimper (1884, 1888, 1898) asserted that vascular epiphytes arose from lineages adapted to the shaded understories of tropical forests, while Pittendrigh (1948) argued that epiphytic bromelioids and tillandsioids evolved from sun-adapted ancestors native to dry, open habitats. Pittendrigh (1948) described four different ecological types in bromeliads:

- **Type I**—terrestrial species with absorptive roots but lacking absorptive trichomes;
- **Type II**—terrestrial species with absorptive roots and absorptive trichomes on leaf bases;
- **Type III**—terrestrial species or epiphytes with roots that mainly serve as anchors, combined with a tank habit and absorptive trichomes on leaf bases;
- **Type IV**—epiphytes with roots that mainly serve as anchors, no tank, and absorptive trichomes over the entire shoot.

Benzing (2000) subdivided Type III into two categories based on possession of CAM vs. C_3 photosynthesis, and argued that Pittendrigh’s Type IV (atmospherics) evolved mainly via neoteny from Type III species (tank epiphytes and terrestrials). The rationale for the latter is simply that the very small size of the “tanks” (impounding leaf axils) in Type III juveniles precludes them from storing much rainwater—or storing it very long—and that such juveniles often
have a much greater coverage of water- and nutrient-absorptive (and light-reflective) trichomes than the tank-forming adults with a more favorable volume/surface area ratio (see Schulz 1930; Tomlinson 1969; Benzing 1980, 2000; Adams and Martin 1986a, b, c; Reinert and Meirelles 1993; Benzing et al. 2000b).

Phylogenetic reconstruction of ancestral character states at the generic level confirmed the derivation of atmospheric epiphytes from tank species in Tillandsioideae (Benzing et al. 2000a). The cpDNA restriction-site phylogeny for Brocchinia (Givnish et al. 1997) places Type I in B. prismatica and all but one species of the next-divergent Melanacrae clade. These taxa occur on thin sands and sandstone, in well-lit microsites that receive abundant rainfall. The earliest tank-formers in two lineages (B. paniculata, B. micrantha) are terrestrial arborescent species with large leaves, voluminous leaf axils, and absorptive trichomes and adventitious roots in those axils (Givnish et al. 1997). These species grow in openings in cloud forests at intermediate elevations (ca. 800–1500 m); their highly unusual growth form corresponds to Type II, but again is native to rainy, not arid habitats. Type III taxa—with unusually large and/or dense absorptive trichomes and (in three of four cases) reduced root systems—include two carnivorous species (B. hechtioides, B. reducata), one ant-fed myrmecophyte (B. acuminate), and one tank epiphyte (B. tatei). Molecular data imply epiphytism evolved from carnivory (Givnish et al. 1997); selection for a tank habit and absorptive trichomes to capture nutrients in a moist, wet, nutrient-poor environment represents a pathway consistent with neither the Schimper or Pittendrigh hypotheses (Givnish et al. 1984, 1997; Benzing et al. 1985; Benzing 2000). Reliance on live, desiccation-intolerant trichomes presumably made the atmospheric habit inaccessible to Brocchinia. In Tillandsioideae, the basal position of Catopsis, then Glomeropitcairnia in an extensive set of ndhF sequences (Terry et al. 1997b) is potentially consistent with the Brocchinia scenario, given that Catopsis berteroniana is also carnivorous (Fish 1976; Frank and O’Meara 1984). However, data on relationships within Catopsis are not yet available. The pathway to tank epiphytism in bromelioids is unclear, given the initial appearance of epiphytism in the large (and potentially poly- or paraphyletic) genus Aechmea.

The evolution of the epiphytic habit in Tillandsioideae and Bromeliioideae is likely to have accelerated speciation simply through effects on dispersability and range size. In a survey of 172 bromeliad species in Bolivia, Kessler (2002a) found that range size is greater (a) in species with fleshy fruits or plumose seed than in those with winged seeds, (b) in epiphytes than in terrestrial species, and (c) in species at lower elevations than at high elevations. The epiphytic habit—and life on ephemeral microsites atop twigs and branches within a given range of diameters—selects for strong dispersal ability (Benzing 1980). Tillandsioids and bromelioids possess plumose seeds and baccate fruits, the most effective means of seed dispersal. The epiphyte Brocchinia tatei has a fringed seed appendage approaching the tillandsioid condition compared with the bicaudate wing seen in congeners (Smith and Downs 1974; Givnish et al. 1997). Epiphytism not only opened a new spectrum of ecological resource to partition locally, it allowed bromelioids and tillandsioids to disperse widely and speciate along the length of the Andes into Central America. Epiphytism is especially favored in cloud forests at middle elevations. Given the greater dissection of habitats at such elevations by drier, lower valleys, it is not surprising that range size decreases with elevation (Kessler 2002b), or that closely related species at middle elevations have peripatric ranges that abut near deep Andean valleys (e.g., Berry 1982 [Fuchsia]; Molau 1988 [Calceolaria]; Norman 2000 [Buddleja]). The ability of a lineage to invade a wide geographic area—especially the latitudinally extensive, topographically complex, and climatically intricate Andean cordilleras (Luteyn 2002; Young et al. 2002), coupled with a tendency to speciation at small spatial scales at middle elevations, should lead to high levels of species diversity at continental scales. The much greater diversity of (mainly epiphytic) Ericaceae in the Andes (586 spp.) vs. the Guayana Highlands (71 spp.) (Luteyn 2002) is consistent with this argument. The narrow endemicism of high-elevation species in groups like Deuterocohnia and Puya is consistent with the general patterns documented by Kessler (2002a); presumably, the relatively low diversity of such groups (ca. 20–100 spp.) reflects the general drop in plant species richness in exceptionally dry or high habitats.

Avian pollination, primarily by hummingbirds, arose at least twice, and has persisted in association with invasion of mid- to high-elevation communities (Guazmania–Tillandsia–Vriesea and many Bromeliioideae in cloud forests, Puya, Abromeitiella, and Deuterocohnia in Andean grasslands, scrub, and puna), low-elevation rain forests (Pitcairnia), and mid to low elevation arid and semi-arid habitats (Dyckia). Pollination by thermoregulating birds is likely to be favored by wet and/or cool conditions at higher elevations, in which many insect groups are likely to be less active and effective. Ornithophily is indeed the dominant pollination mode at high elevation and in wet regions in bromeliads of the Bolivian Andes (Kessler and Kromer 2000), and shifts to ornithophily in Lobeliaceae on different continents and islands have mainly occurred with the invasion of cloud forests (Givnish 1998). Many epiphytic Ericaceae in the Andes, which inhabit the same cloud forests as many tillandsioids and bromelioids, have also evolved hummingbird pollination (Luteyn 2002). The relationship between bird pollination and habitat, however, is not one-to-one in Bromeliaceae. It is puzzling that ornithophily did not evolve in Brocchinioideae and Lindmarioideae, even though these groups are largely restricted to cool, wet habitats at mid to high elevations, and species in other families in those habitats are pollinated by birds. The short stature of plants in such groups might, however, select against ornithophily, by exposing avian pollinators to terrestrial predators. Bird-pollinated Abromeitiella and Deuterocohnia are even shorter in stature; however, terrestrial predators may not be a significant threat in their high-elevation tundra environment.

Based on an extensive DNA-DNA hybridization study, Bleiweiss (1998) inferred that the initial divergence among modern lineages of hummingbirds (Trochilidae) occurred in the early Miocene, roughly 18 Mya. Bleiweiss argues that the extraordinary morphological isolation of hummingbirds from swifts, their closest living relatives, is due to the fact that 40 My elapsed between the divergence of Trochilidae from swifts and the diversification of the modern crown group—paralleling the rationale we have given for the sim-
ilar isolation of bromeliads from other monocot groups. Bleiweiss (1998) dated the divergence of the two major Andean clades of hummingbirds to about 12 Mya, which coincides rather precisely with our estimates for the origins of Guzmania–Tillandsia–Vriesea and Pitcairnioideae–Puyioideae–Bromelioidae, the two major clades of hummingbird-pollinated bromeliads, with many in this group being Andean in distribution and epiphytic in habit. Berry et al. (2004) have independently dated the origin of the large, mainly hummingbird-pollinated Fuchsia sect. Fuchsia at 22 Mya, about the time of the initial diversification of the troichlid crown group.

The independent evolution of four to six leaf and trichome anatomical traits in three lineages adapted to dry conditions—Hechtia, Puya, and the Xeric clade—is one of the most striking cases of concerted convergence documented to date. Other examples include (1) the retention of inconspicuous flowers, fleshy fruits, broad leaves, net venation, and rhizomes in shade-dwelling members of the core Lilies, and evolution of visually conspicuous flowers, capsular fruits, narrow leaves, parallel venation, and bulbs in relatives inhabiting open microsites (Patterson and Givnish 2002), and (2) the evolution of fleshy fruits and net venation in more than a dozen lineages of monocots, almost always associated with the invasion of shaded forest understories (Givnish et al. 2006). Concerted convergence in the core Lilies confounds phylogenetic analyses based on morphology, and unites species with each suite of characteristics. Concerted convergence in Bromeliaceae may have the same effect, given that a cladistic analysis of relationships within the former Pitcairnioideae based on phenotypic traits identifies two clades characterized by the presence vs. absence of CAM photosynthesis and the drought-adapted states of the leaf and trichome traits evaluated in this paper (see phylogenies presented by Varadarajan and Gilmartin 1988; Reinit et al. 2003).

Finally, the extraordinary radiation in growth form and mode of nutrient capture in Brocchinia may reflect not only the adaptive challenges and opportunities produced by life in rainy, humid, extremely nutrient-poor habitats (Givnish et al. 1997), but also an amount of time for differentiation among current-day lineages within Brocchinia equal to that (ca. 17 My) for differentiation of almost all the rest of the genera and species in the family as a whole (Fig. 2). Brocchinia represents a kind of “Darwin’s finches” sister to the rest of the family, in which many of the growth forms and mechanisms of nutrient acquisition that arose across a family of ca. 2600 species and 53 genera evolved within a small set of roughly 20 species. It continues to offer an important system for exploring adaptive radiation and geographic diversification. Similar opportunities are offered by the remarkable variation in growth form and pollination syndrome in Tillandsia and in the higher tillandsioids more generally in Pitcairnia, and in Puya. Several of these groups are now being studied intensively using molecular systematics (Terry et al. 1997b; T. Evans and G. Brown pers. comm; M. Barfuss and W. Till pers. comm; P. Foderie pers. comm.), and should produce several new insights into the ecology, evolution, biogeography, and systematics of Bromeliaceae.

ACKNOWLEDGMENTS

This study was supported by a Vilas Research Associateship from the University of Wisconsin and NSF grant IBN-9904366 to TJJ; by grants to TJJ and KJS from the National Science Foundation (DEB-9306943) and the National Geographic Society; and by NSF grant DEB-9981587 to PEB, TJJ, and KJS. A grant from the Smithsonian Institution to Vicki Funk helped support a helicopter expedition to several Venezuelan tepuis. Bruce Holst and Harry Luther of Selby Botanical Garden enthusiastically assisted in providing leaf material for several species included in this study. We thank Basil Stergios, Gustavo Romero, Charles Brewer, and Fabian and Armando Michelanelli for helping arrange permits and logistics in Venezuela. Julio Betancur provided material of Brocchina serrata from Cerro de Circasia in Colombia. James Smith and Angel Fernández helped collect specimens on two expeditions to Venezuelan Amazonas.
